ReliefMSS: a variation on a feature ranking ReliefF algorithm

Salim Chikhi* and Sadek Benhammada

Computer Science Department, Mentouri University, MISC Laboratory, route de Aïn El Bey Constantine 25017, Algeria E-mail: salim_chikhi@umc.edu.dz E-mail: Benhammada@yahoo.fr *Corresponding author

Abstract: Relief algorithms are successful attribute estimators. They are able to detect conditional dependencies between attributes and provide a unified view on the attribute estimation. In this paper, we propose a variant of ReliefF algorithm: ReliefMSS. We analyse the ReliefMSS parameters and compare ReliefF and ReliefMSS performances as regards the number of iterations, the number of random attributes, the noise effect, the number of nearest neighbours and the number of examples presented. We find that for the most of these

parameters, ReliefMSS is better than ReliefF.

Keywords: feature selection; relief algorithms; number of nearest neighbours.

Biographical notes: S. Chikhi received his PhD in Computer Science from University of Constantine, in 2005. He is currently Assistant Professor at the Department of Computer Science, Mentoury University, Constantine, Algeria. His current research interests include machine learning, hybrid systems and soft computing applications.

S. Benhammada is a Master degree student in Computer Science at the University of Constantine (Algeria). His current research work focuses on machine learning and neural networks.

1 Introduction

Many factors affect the success of machine learning on a given task. The representation and quality of the example data is first and foremost. Theoretically, having more features should result in more discriminating power. However, practical experience with machine learning algorithms has shown that this is not always the case (Hall, 1999). Not all the available features are pertinent. It is possible that some correspond to the noise. They can also bring few information, be correlated or even useless to the system for the fulfilment

of its task. According to Jain et al. (2000), the performance of a classification system depends strongly on relations between the number of used samples, the number of considered features and the system complexity. Indeed, to obtain a powerful system, it is necessary to have enough great number of samples, which represent well the different phenomena to model, so as to estimate correctly its parameters. Moreover, an exponential relation binds the number of samples to the number of characteristics used by the system: for the addition of a new characteristic, the number of samples must be increased in an exponential way. These different remarks show clearly that it is necessary to restrict the number of considered features, during a system construction, so as to optimise its performances. By this fact, the attribute selection is an active research domain since many decades. A lot of works and publications deal with these techniques which are applied to many areas (Grandidier, 2003). The ReliefF algorithm is one of these techniques; it is a successful attribute estimator. Unlike the majority of the heuristic measures for estimating the quality of the attributes, the Relief algorithms do not make the assumption of conditional independence between attributes. They are able to detect conditional dependencies between attributes and provide a unified view on the attribute estimation. In addition, their quality estimates have a natural interpretation. While they have commonly been viewed as feature subset selection methods that are applied in prepossessing step before a model is learned, they have actually been used successfully in a variety of settings, e.g., to select splits or to guide constructive induction in the building phase of decision tree learning, as the attribute weighting method and also in the inductive logic programming (Robnik-Sikonja and Kononenko, 2003a). Fu and Wang (2005) have carried out a data dimensionality reduction and rule extraction techniques based on a novel separability-correlation measure for ranking the importance of attributes. Other researchers have used the ReliefF algorithm to select genes for cancer classification (Wang and Makedon, 2004), to select feature for image classification (Campedel and Moulines, 2004), to select features from the multi-wavelength data (Zhang, 2004), and as an attribute estimation measure for building classification trees in the data analysis of a controlled clinical study of the chronic wound healing acceleration as a result of electrical stimulation (Robnik-Sikonja et al., 2003b). Original Relief as developed by Kira and Rendell (1992a) can deal with discrete and continuous attributes and is limited to only two-class problems. This basic algorithm was quickly extended by Kononenko (1994). His ReliefF algorithm is more robust than the original because it selects a set of nearby hits and a set of nearby misses for every target sample and averages their distances. Many extensions of ReliefF have been proposed to deal with noisy, incomplete, and multi-class data sets (Bins and Draper, 2001; Sun and Li, 2006). In this paper, we present the ReliefMSS. We first present the original Relief and ReliefF algorithms in Section 2, and then present, in Section 3, our ReliefMSS approach which is a new variant of the ReliefF algorithm. In Section 4, to understand the ReliefMSS behaviour, we examine and analyse its robustness regarding to parameters like the number of the nearest neighbours, the distances and the number of iterations. In Section 5, we compare the performances of both ReliefF and ReliefMSS algorithms according to the number of examples, the noise, the number of iterations, the number of random attributes and the number of nearest neighbours. In Section 6, we summarise the results obtained and speak about future works.

2 Relief and ReliefF algorithm

A key idea of the original Relief algorithm (Kira and Rendell, 1992b), given in Figure 1, is to estimate the quality of attributes according to how well their values distinguish between instances that are near to each other. For that purpose, given a randomly selected instance Ri (line 3), Relief searches for its two nearest neighbours: one from the same class, called *nearest hit H*, and the other from the different class, called *nearest miss M* (line 4). It updates the quality estimation W[A] for all attributes A depending on their values for Ri, M, and H (lines 5 and 6). If instances Ri and H have different values of the attribute A separates two instances with the same class which is not desirable, so we decrease the quality estimation W[A]. On the other hand, if instances Ri and M have different values of the attribute A, then the attribute A separates two instances with different class values which is desirable, so we increase the quality estimation W[A]. The whole process is repeated for M times, where M is a user-defined parameter.

Figure 1 Pseudo code of Relief algorithm

```
Input: for each training instance a vector of attribute values and the class value

Output: the vector W of estimations of the qualities of attributes

1. set all weights W[A] := 0:0;

2. for i := 1 to m do begin

3. randomly select an instance Ri;

4. find nearest hit H and nearest miss M;

5. for A := 1 to a do

6. W[A] := W[A]-diff(A,Ri,H)/m+diff(A,Ri,M)/m

7. end
```

Function $diff(A, I_1, I_2)$ calculates the difference between the values of the attribute A for two instances I_1 and I_2 . For nominal attributes, it was originally defined as:

$$diff(A, I_1, I_2) = \begin{cases} 0: & \text{value}(A, I_1) = \text{value}(A, I_2) \\ 1: & \text{otherwise} \end{cases}$$
 (1)

and for numerical attributes as:

$$diff(x_i, d, \text{hits}_j) = \frac{|\text{value}(A, I_1) - \text{value}(A, I_2)|}{\max(A) - \min(A)}.$$
 (2)

Max and min designate, respectively, the maximal and the minimal value that attribute *A* can hold over the data set. The function *diff* is also used for calculating the distance between instances to find the nearest neighbours. The original Relief can deal with nominal and numerical attributes. However, it cannot deal with incomplete data and is limited to two-class problems. Its extension, which solves these and other problems, is called ReliefF (Kononenko, 1994).

The ReliefF (Relief-F) algorithm (Kononenko, 1994) (see Figure 2), which is not limited to two class problems, is more robust and can deal with incomplete and noisy data. Similar to Relief, ReliefF randomly selects an instance Ri (line 3), but then searches for k of its nearest neighbours from the same class called nearest hits H_i (line 4), and also

4

k nearest neighbours from each of the different classes called nearest misses M_j (C) (lines 5 and 6). It updates the quality estimation W[A] for all attributes A depending on their values for Ri, hits H_j and misses M_j (C) (lines 7–9). The update formula is similar to that of Relief (lines 5 and 6 on Figure 1), except that we average the contribution of all the hits and all the misses. The contribution for each class of the misses is weighted with the prior probability of that class P(C) (estimated from the training set). Since we want the contributions of hits and misses in each step to be in [0,1] and also symmetric (we explain reasons for that below), we have to ensure that misses' probability weights sum to 1. As the class of hits is missing in the sum, we have to divide each probability weight with factor $1-P(class(R_i))$ (which represents the sum of probabilities for the misses' classes). The process is repeated for m times. Selection of k hits and misses is the basic difference to Relief and ensures greater robustness of the algorithm concerning noise. User-defined parameter k controls the locality of the estimates.

Figure 2 Pseudo code of ReliefF algorithm

```
Input: for each training instance a vector of attribute values and the class value

Output: the vector W of estimations of the qualities of attributes

1. set all weights W[A] := 0.0;

2. for i := 1 to m do begin

3. randomly select an instance Ri;

4. find k nearest hits Hj;

5. for each class C \neq classe(Ri) do

6. from class C find k nearest misses Mj(C);

7. for A := 1 to a do

8. W[A] := W[A] - \sum_{j=1}^{k} \frac{diff(A, R_j, H_j)}{(m, k)}
+ \sum_{c \neq class(R_j)} \frac{P(c)}{1 - P(class(R_j))} \sum_{j=1}^{k} \frac{diff(A, R_j, M_j(C))}{(m, k)}

9. end
```

3 ReliefMSS: the proposed variant

In the same way as ReliefF, ReliefMSS selects randomly an instance R_i (Figure 3, line 3), and research the k nearest neighbours of the same class as R_i H_j (Figure 3, line 4,), and also the k nearest neighbours in each of the other classes, $M_j(C)$ (Figure 3, lines 5 and 6). However, the update of the weight W[A] for any attribute A is not only made by its values for the instances R_i , H_j and $M_j(C)$, but also by the values of the other attributes, as explained in what follows:

• If the difference between the values of the attribute A for the selected instance R_i and a nearest neighbour of the same class H_j : $diff(A, R_i, H_j)$ (equations (1) and (2)) is greater than the values differences average of the other attributes for these two instances $DM(A, R_i, H_j)$ (equation (3)), then the attribute A will undergo a decrease of its quality according to the distance between $diff(A, R_i, H_j)$ and $DM(A, R_i, H_j)$ (Figure 3, line 8).

- If the difference between the values of the attribute A for the selected instance R_i and a nearest neighbour of another class M_j (C): $diff(A, R_i, M_j$ (C)) (equations (1) and (2)) is greater than the values differences average of the other attributes for these two instances DM(A, Ri, Mj (C)), then the attribute A will undergo an increase of its quality according to the distance between $diff(A, R_i, H_j)$ and $DM(A, R_i, H_j)$ (equation (3)) and Figure 3, line 9).
- We do not make any change in other cases.

Figure 3 Pseudo code of ReliefMSS

```
Input: for each training instance a vector of attribute values and the class value

Output: the vector W of estimations of the qualities of Attributes

1. set all weights W[A] := 0.0;

2. for i := 1 to m do begin

3. randomly select an instance Ri;

4. find k nearest hits Hj;

5. for each class C \neq classe(Ri) do

6. from class C find k nearest misses Mj(C);

7. for A := 1 to a do

8. W[A] := W[A] - \sum_{diffH > DMH}^{j=1,k} \frac{diffH - DMH}{(m.k)}

9. + \sum_{c \neq class(R_i)} \frac{P(c)}{1 - P(class(R_i))} \sum_{diffM > DMM}^{j=1,k} \frac{diffM - DMM}{(m.k)}
```

The function $DM(A_j, I_1, I_2)$ calculates the values differences average of all attributes except attribute A for the two instances I_1 and I_2 . It is defined by:

$$DM(A_j, I_1, I_2) = \frac{1}{a - 1} \sum_{i \neq j}^{i = 1, a} diff(A_i, I_1, I_2).$$
(3)

For the legibility of the algorithm we put:

- $diff(A, R_i, H_i) = diffH$
- $diff(A, R_i, M_i(C)) = diffM$
- $DM(A, R_i, H_i) = DMH$
- $DM(A, R_i, M_i(C)) = DMM$.

We can explain the proposed manner to change attributes' weights by the following:

For the negative updates, the condition *diffH* > *DMH* and the value of *DMH* (Figure 3, line 8) allow to diminish the negative update of the attributes which takes a close value for the instances from the same class (important attributes).

For the positive updates, the condition diffM > DMM and the value of DMM (Figure 3, line 9) allow to diminish the positive updates of the attributes which takes a close value for the instances from different classes (insignificant attributes).

4 ReliefMSS behaviour

In this section, we consider different ReliefMSS parameters to understand the behaviour of the algorithm: the number of nearest neighbours to be used, the distance between the instances, and the minimal number of iterations needed.

4.1 The number of nearest neighbours

To study the ReliefMSS algorithm behaviour as regards the number of nearest neighbours (nnn), we generated 200 instances of the parity problem: $(A \oplus A_2)$ (Robnik-Sikonja et al., 2003a), with ten random attributes, in a way that each of two classes contains exactly 100 instances (so that we can vary the nnn of 1 until 99). We observed the estimations of the attributes according to nnn. Figures 4 and 5 show respectively ReliefF and ReliefMSS estimations according to the considered nnn. We notice that the estimations of both algorithms of one of the informative attributes become more and more short-sighted with the growth of nnn; however, ReliefMSS discerns between the informative attribute and the insignificant attribute even for 99 nearest neighbours, differently from the ReliefF algorithm whose estimation of the informative attribute becomes finally imperceptible of that of the insignificant attribute.

Figure 4 ReliefF estimates according to the number of nearest neighbours on $(A_1 \oplus A_2)$ problem (see online version for colours)

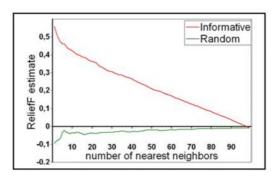

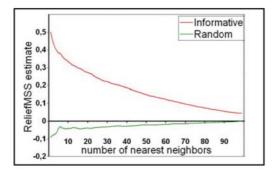

Figure 5 ReliefMSS estimates according to the number of nearest neighbours on $(A_1 \oplus A_2)$ problem (see online version for colours)

We also examine the ReliefMSS estimations according to nnn in the Boolean problem defined by:

$$C = (A_1 \oplus A_2) \vee (A_3 \wedge A_4). \tag{4}$$

We generate iteratively 200 instances in such a way as every class contains exactly 100 instances. Figures 6 and 7 show the results obtained for ReliefF and ReliefMSS, respectively.

We know that A_1 and A_2 are more important than A_3 and A_4 for the determination of a class. ReliefMSS recognises this even for 99 nearest neighbours (the greatest possible number of nearest neighbours); on the other hand, the algorithm ReliefF recognises this to only 80 nearest neighbours.

Figure 6 ReliefF estimates according to the number of nearest neighbours on problem define 1 by equation (4) (see online version for colours)

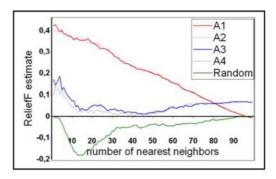

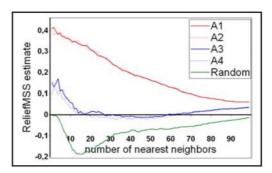

Figure 7 ReliefMSS estimates according to the number of nearest neighbours on problem defined by equation (4) (see online version for colours)

4.2 Taking the distances into account

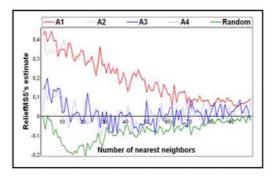

When we take the nearest neighbours we reduce the risk of the following pathological case:

we have a large number of instances and a mix of nominal and numerical attributes where numerical attributes prevail; it is possible that all the nearest neighbours are closer than 1 so that there are no nearest neighbours with differences in values of a certain nominal attribute. If this happens in a large part of the problem space this attribute gets

zero weight (or at least small and unreliable one) (Robnik-Sikonja et al., 2003a). However, the use of a large nnn causes a degradation of the weights assigned to the important attributes (Figures 5 and 7). By using fewer instances, less iterations, complex problems or noised data, the algorithm becomes less robust regarding to the nnn, and we face the risk of having incompatible estimations with the importance of the attributes.

In the example of Figure 7, we selected all the instances (m = n), which makes it possible to obtain relatively stable weights. Figure 8 represents the weights of the attributes according to the nnn for the same problem (equation (4)), such as the number of iterations is m = 30.

Figure 8 ReliefMSS estimates according to the number of nearest neighbours on problem defined by equation (4) (m = 30) (see online version for colours)

We note that the weights assigned to the attributes become unstable; this increases the risk to have weights incompatible with the importance of the attributes with the growth of nnn.

One of the solutions to this problem is taking the distances into account (Robnik-Sikonja et al., 2003a). It is involved in taking a large nnn by giving more impact to the nearest instances. The estimate of their impact is then inversely proportional to their distances of the point in question. ReliefMSS can be adjusted to taking the distances into account by changing the way of the weights update (Figure 3, line 8 and 9). Figure 9 represents the ReliefMSS estimations considering the distance for the same problem (equation (4)) with 200 instances, 30 iterations, and the distance factor σ = 5. Sigma is a user-defined parameter, we tried different values of sigma, and we conclude that 5 is a good and convenient value

$$W[A] := W[A] - \frac{1}{m} \sum_{diffH > DMH}^{j=1,k} (diffH - DMH).d(R_i, H_j)$$

$$+ \frac{1}{m} \sum_{c \neq class(R_i)} \frac{P(c)}{1 - P(class(R_i))} \sum_{diffM > DMM}^{j=1,k} (diffM - DMM).d(R_i, M_j(C)).$$
(5)

The distance factor of two instances $d(I_1,I_2)$ is defined by:

$$d(i,j) = \frac{d_1(i,j)}{\sum_{l=1}^k d_1(i,l)}.$$
(6)

such as:

$$d_1(i,j) = e^{\frac{-rank(R_i,I_j)}{\sigma}}. (7)$$

By comparing Figure 8 with Figure 9, we notice that by considering the distance, the robustness of ReliefMSS has been strengthened with regards to nnn.

4.3 The number of iterations

Figure 10 shows the estimates of ReliefMSS according to the number of iterations for the Boolean problem defined by equation (4). We note that with a small number of iterations the weights assigned to the attributes are not stable any more. For example, the quality difference between the attribute A_3 and the random attribute is not resolved until around 71 iterations, the quality difference between the attributes A_1 and A_3 is not resolved until around 84 iterations. With the growth of the number of iterations, the weights assigned to the attributes approach the stable values more and more.

Figure 9 ReliefMSS estimates considering the distances according to the number of nearest neighbours on problem defined by equation (4) $(m = 30, \sigma = 5)$ (see online version for colours)

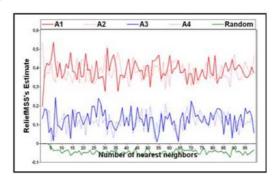

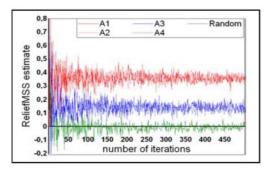

Figure 10 ReliefMSS estimates according to the number of iterations on problem defined by equation (4) (see online version for colours)

The random selection of m instances (Figure 3, line 2) in a space of the unknown problem can be in favour of the non-representative instances rather than the most representative ones.

If the dataset is reasonably large, the solution consists in selecting all the instances. If we have a very large data set, the selection of all the instances is not possible because of the increasing of calculations complexity. In this case, the solution consists of the use of the selective sampling approach which attempts to select only representative instances with a high probability to be informative in determining feature relevance (Liu et al., 2004).

5 Performance analysis

In this section, we compare ReliefMSS and ReliefF performances as regards the influence of the next parameters:

- the number of examples
- the robustness concerning the noise
- the number of iterations which we need for a reliable estimation
- the number of random attributes
- the number of nearest neighbours (nnn).

We use artificial datasets because we want to control the environment: in real-world datasets, we do not fully understand the problem and the relation of the attributes to the target variable. Therefore, we do not know what a correct output of the feature estimation should be and we cannot evaluate the quality estimates of the algorithms. We use the following measures defined in Robnik-Sikonja and Kononenko (2003a):

Separability is the difference between the lowest estimate of the important attributes and the highest estimate of the unimportant attributes.

$$S = W_{\text{Iworst}} - W_{\text{Rbest.}} \tag{8}$$

We say that a heuristics is successful in separating between the important and unimportant attributes if s > 0.

 $Usability \ u$ is the difference between the highest estimates of the important and unimportant attributes.

$$u = W_{\text{Ibest}} - W_{\text{Rbest}}. \tag{9}$$

5.1 The number of examples

To examine the influence of the number of examples available on the estimates of ReliefMSS, we applied the algorithm to the various artificial problems described in Robnik-Sikonja and Kononenko (2003a), the objective being the search for the minimal necessary number of examples so that the separability (Usability) is positive. Thus, for each problem we varied the number of examples, and for each number of examples we repeated the calculation of the weights of the attributes and their values of S and U 100 times, until the acquisition of the number of examples allowing to have a separability (Usability) greater than in 99 experiments at least.

In table 1, the two right-hand side columns represent the numbers of examples necessary for ReliefF, while the two left-hand columns represent the example numbers necessary for ReliefMSS. We note that both algorithms require a small number of examples to separate the important attributes from the insignificant ones (separability) and a smaller number to separate an important attribute from the unimportant ones (Usability). The number of necessary examples increases with the growth of the problem difficulty (variation). ReliefMSS requires fewer examples than ReliefF on four problems for the separability and four problems for the usability and requires more examples on two problems for the separability and two problems for the usability. However, the difference with the number of necessary examples for the two algorithms remains light for all the problems.

 Table 1
 Results of varying the number of examples

	Rel	iefMSS	ReliefF		
Problem	S	U	S	U	
Simple-Bool	170	42	165	42	
Modulo-2-2-c	38	31	40	35	
Modulo-2-3-c	120	77	141	78	
Modulo-2-4-c	305	240	305	240	
Modulo-5-2-c	95	77	104	100	
Modulo-5-3-c	547	492	545	508	
Modulo-10-2-c	245	202	202	198	
MONK1	61	49	73	46	

5.2 The noise percentage

To compare the robustness of ReliefMSS and ReliefF concerning the noise, we consider the same previous problems, the objective being to find the maximum noise percentage that the algorithms can support. Thus, for each problem, we varied the noise percentage by changing some percentage of classes values by random values. For each noise percentage, we repeated the calculation of the attribute weights and their *S* and *U* values 100 times, until obtaining the maximal noise percentage to maintain a positive separability (usability) in 99 experiments at least. The number of instances used for each problem is a number sufficient for the two algorithms. For example, the Modulo-5-3-c problem requires 545 instances for ReliefF and 547 instances for ReliefMSS (columns *S* in Table1), whereas the number of instances used is 550.

In the obtained results, shown in Table 2, column #Ex represents the number of instances that have been used. We can note that ReliefMSS and ReliefF show a noise tolerance even with the minimal number of instances necessary to separate the important attributes from the unimportant ones. The ReliefMSS noise tolerance is equivalent to that of ReliefF for the majority of problems. However, it presents more tolerance for the problems Modulo-5-2-C and Modulo-5-3-C.

 Table 2
 Results of varying the noisy prediction value

1		Rel	iefMSS	ReliefF	
Problem	# <i>Ex</i>	S	U	S	и
Bool-Simple	170	5	70	5	75
Modulo-2-2-c	45	2	20	2	15
Modulo-2-3-c	145	10	25	10	25
Modulo-2-4-c	305	30	25	30	25
Modulo-5-2-c	105	45	50	15	35
Modulo-5-3-c	550	15	30	10	20
Modulo-10-2-c	245	20	20	20	20
MONK1	75	15	35	15	35

Table 3 shows the noise percentages for ReliefMSS and ReliefF, where the number of examples used for each problem is twice the number of examples used in Table 2. We note that the ReliefMSS noise tolerance increases considerably in all the problems.

Table 3 Results of varying the noisy prediction value using twice the number of examples used in Table 2

	# Ex x 2	ReliefMSS		ReliefF	
Problem		S	и	S	и
Bool-Simple	340	15	75	15	75

Modulo-10-2-c	490	45	50	50	55
MONK1	150	40	65	50	65

5.3 The number of iterations

To examine the influence of the iteration number on the ReliefMSS estimates, we also consider the same preceding problems, the objective being to find a minimal number of iterations so that the separability (Usability) remains positive. Thus for each problem we varied the number of iterations, and for each number of iterations we repeated the calculation of the attributes weights and their values of S and U 1000 times, until the acquisition of the minimal number of iterations allowing to have a separability (Usability) positive in 999 experiments at least.

Table 4 shows the obtained results; we note that ReliefMSS requires less iteration than ReliefF for the majority of the problems. We repeated the experiment by multiplying the examples number used in Table 4 by 2.

		ReliefMSS		ReliefF	
Problem	# Ex	S	и	S	и

Modulo-10-2-c	490	21	20	17	17
MONK1	150	32	3	28	3

5.4 The number of random attributes

To examine the influence of the number of random attributes on the estimates of ReliefMSS, we used the same previous problems except Monk1 problem (the number of attributes in its data sets is fixed). The objective is to find the maximal number of random attributes allowing separability (utility) to be preserved as positive. Thus, for every problem we varied the number of random attributes, and for every number of random attributes, we repeated the calculation of the attribute weights and their s and u values 100 times, until obtaining the maximal number of random attributes allowing to preserve a separability (utility) positive in at least 99 experiments.

Table 6 shows the obtained results; we notice that we can give only a moderate number of random attributes to separate all the important attributes from the insignificant attributes (separability). This number is bigger to separate an important attribute from the unimportant attributes (Usability). ReliefMSS and ReliefF support the same number of random attributes for the majority of the problems.

Modulo-10-2-c	245	21	21	14	21

5.5 The number of nearest neighbours (nnn)

To examine the robustness of ReliefMSS to nnn, we also used the same preceding problems. The objective is to find the maximal nnn allowing to maintain a positive separability (usability). Thus, for each problem we varied nnn, and for each nnn we repeated the calculation of the attributes weights and their values of S and U 100 times, until the acquisition of the maximal nnn allowing to have a separability (Usability) positive in 99 experiments at least. Table 7 shows the obtained results, symbol '-' means that the algorithm resists even with the greatest possible nnn, we notice that ReliefMSS is more robust than ReliefF for all the problems

 Table 7
 Results of varying the number of nearest neighbours

	# Ex	ReliefMSS		ReliefF	
Problem		S	и	S	и
Bool-Simple	170	34	-	29	_
Modulo-2-2-c	45	21	_	16	18

Modulo-10-2-c	245	15	18	14	15
MONK1	75	13	_	10	_

6 Conclusion

To update an attribute weight, ReliefF uses only the differences between the values of this attribute for the selected instance and the nearest neighbours of this instance. The attribute will undergo a reduction of its quality if there is a difference between its values for the selected instance and a nearest neighbour of the same class. It will obtain an increase of its quality if there is a difference between its values for the selected instance and a nearest neighbour of another class. In this paper, we propose a ReliefMSS

algorithm, which is a variant of ReliefF. To update an attribute weights, we introduce the average of the differences of the values of other attributes. The attribute will undergo a reduction of its quality if the difference between its values for the selected instance and a nearest neighbour of the same class is greater than the values differences average of the other attributes for these two instances. It will obtain an increase in its quality if the difference between its values for the selected instance and a nearest neighbour of another class is greater than the values differences average of the other attributes. A comparison of performances was carried out by using artificial data. ReliefMSS presented better performances than ReliefF, in particular, with regard to the number of nearest neighbours and the number of iterations. We have been encouraged by the obtained results and will consider the use of real-life data. As perspectives, we will try to perform a theoretical analysis of the proposed variant with the use of other measures.
